# Returns to scale, productive efficiency, and optimal firm size evidence from Taiwan's firm data 

YIH-CHYI CHUANG<br>Department of Economics, National Chengchi University, Taipei, Taiwan, ROC

#### Abstract

By using Taiwan's census firm data, this paper estimates and tests the variable returns to scale hypothesis for aggregate manufacturing and two-digit industries. An efficiency measure is constructed to further examine the size-efficiency relations among two-digit industries. Analysis indicates that increasing returns exist at the aggregate manufacturing level and its magnitude is higher for exporting firms than for nonexporting firms. Moreover, trade is beneficial only for small firms. However, the property of increasing returns diminishes for most of the industries at the two-digit level, particularly for the exporting firms. This sharp comparison between aggregate and two-digit level results suggests that trade is conducive to productivity, and provides an indication of the specific form of technology spillovers among firms and across industries. Further investigation of the relationship between productive efficiency and firm size renders the result that optimal firm size is small for exporting firms in most industries, particularly in the most export-oriented ones. The technology spillover effect among firms and across industries is likely the reason for being small and efficient. Our results also indicate that an industry-wide spillover effect across firms within the same industry is roughly one-sixth of the firm-specific export-induced learning effect. Findings in this study provide valuable insight into Taiwan's economic development and also provide a development strategy for developing countries to follow.

## I. INTRODUCTION

Economic development generally implies a process of industralization during which predominance within the industrial structure shifts from the traditional agricultural sector to modern manufacturing. Moreover, the dynamic process of industrialization involves a shift in production structure within the manufacturing sector. Both facets of this persistent structural change are keys to sustaining economic growth. Thus, investigating the productivity and sizeefficiency relations among different industries becomes essential to more thoroughly understanding economic growth.

After the surge of endogenous growth theory in the mid 1980s, numerous models have pointed out the importance of increasing returns or externalities to sustain a country's long run growth (see, for example Romer, 1986; Grossman and Helpman, 1991; Barro and Sala-i-Martin, 1995 and
references therein). Therefore, increasing returns to scale in manufacturing industry might be a prominent factor for industrialization and economic growth. However, Blomstrom and Wolff (1993) indicated that the new growth literature has largely neglected the discussion of the transformation and the technology diffusion within countries and industries. Using Mexican manufacturing data, they found that most of the variation in labour productivity across plant class sizes can be attributed to differences in capital intensity and that the variation in TFP levels across size classes tends to be small. This result corresponds to Meller (1976) and Ramaswamy's (1994) findings of no systematic differences in technical efficiency between large and small establishments for Chilean establishments and Indian industry, respectively.

In this study, we estimate the returns to scale and examine size-efficiency relations of the manufacturing sector by using Taiwan's firm data. We find weak increasing returns at the
aggregate manufacturing level. Comparing exporting versus nonexporting firms, we find that exporting firms in aggregate generally exhibit stronger increasing returns and a higher capital intensity than nonexporting firms. In a twodigit industry level, however, significant variable returns to scale can only be found in some industries: namely, food, textiles, chemicals, chemical products, plastic products, and basic metal industries. By using our efficiency measure, we find that 12 out of 20 industries have a small optimal firm size for the exporting firms. Such evidence should perhaps come as little surprise, given that SME's predominate in Taiwan's for-export markets.

The rest of the paper is organized as follows. Section II provides a brief description of the Taiwanese economy; Section III presents the empirical model; Section IV discusses data and the estimation method employed; Section V summarizes the estimation results for aggregate manufacturing and two-digit industries. Concluding remarks are finally made in Section VI.

## II. THE TAIWANESE ECONOMY

Since the end of World War II, Taiwan's economy has grown by leaps and bounds, and has successfully transformed from an agriculturally-oriented economy to an industrially-oriented one, with a subsequent rise of the advanced service industry appearing still more recent. From 1953 to 1993, the annual average economic growth rate in Taiwan measured an impressive $8.7 \%$ ( $6.3 \%$ for per capita GNP). The share of agriculture in GDP was $34.45 \%$ in 1953, and has declined steadily over time to reach $3.46 \%$ by 1993. The share of industry was only $19.39 \%$ in 1953 , and then increased annually, surpassing agriculture in 1962. It reached its highest value of $47.64 \%$ in 1986 and then slightly declined beginning in the late 1980s. Production structure has changed dramatically as well, as evident in the shift of the leading industry from food to textiles, and then to electrical and electronic machinery. Obviously, Taiwan's rapid economic growth is synonymous with its successful industrialization process.
As the government policy passed from import substitution in the early 1950s, through export-promotion beginning in the late 1950s, and then onto more aggressive trade liberalization in the 1980s, the dependence of Taiwan's economy on foreign trade has increased tremendously. From 1960 to 1993, the average annual growth rate of real exports was $15.4 \%$ ( $13.7 \%$ for real imports). The trade structure also changed enormously. The share of industrial products was only $8.1 \%$ in 1952 , but later surged to $46 \%$ in 1965 and $78.6 \%$ in 1970; thereafter, following a moderate increasing trend, it reached $96 \%$ in 1993. As for Taiwan imports, during 1952-93, over $60 \%$ of all imports were
agricultural and industrial raw materials due to the scarcity of natural resources. The share of capital goods in total annual imports increased from $14.2 \%$ in 1952 to $29.3 \%$ in 1965, hovered above $30 \%$ until 1975, and then gradually declined to $15.45 \%$ in 1993.
As the economy matured and expanded outwardly, private savings also increased. The savings rate (i.e., gross national savings divided by GDP) increased from $15.3 \%$ in 1952 to $32.1 \%$ in 1972 and then remained stable at approximately $33 \%$ through 1990. It was the increase in domestic savings which really enabled the economy to finance its accumulation of physical capital. Since the mid 1970s, however, domestic savings has outpaced domestic investment, reflecting the sustained trade surplus in Taiwan's current account.
Investment in human capital accumulation was also remarkable. The distribution of employed workers having completed primary, secondary, and tertiary schooling was $54.95 \%, 14.87 \%$, and $3.93 \%$, respectively, in 1964 . However, the same figures in 1993 registered $26.09 \%, 51.80 \%$, and $18.04 \%$, respectively, indicating an unequivocal upward shift in the quality of the labour force.
In sum, Taiwan's economic growth over the past four decades has been characterized by successful industrialization, heavy dependence on international trade, and persistent accumulation of capital and improvement in human resources. Hence, Taiwan is definitely a qualified candidate for investigation as a case-study in this paper.

## III. THE EMPIRICAL MODEL

In this study, a Solow-type production function, augmented to include embodied technical change, is adopted to estimate returns to scale. Moreover, we allow the latter to vary as a function of firm size. As indicated in Szpiro and Cette (1994), the Solow production function can be generalized in the following manner:

$$
\begin{equation*}
Y_{i}=A_{j} \cdot \exp \left\{\lambda_{j}\left(E T C_{i}\right)\right] S_{i}^{f_{i}\left(s_{i}\right)} \tag{1}
\end{equation*}
$$

where indices $i$ and $j$ denote the individual firm and sector, respectively; $S_{i}=K_{i}^{\alpha_{i}} L_{i}^{1-\alpha}$ is an index of firm size for firm $i$ in sector $j$, and $s_{i}=\alpha_{j} k_{i}+\left(1-\alpha_{j}\right) l_{i}$ is the logarithm of $S_{i},{ }^{1}$ $Y, K, L$ are the volumes of value added, capital, and labour in production, respectively; $E T C$ represents the embodied technical change, and $\lambda_{j}$ reflects the effect of the embodied technical change; $f_{j}\left(s_{i}\right)$ is a sector-specific polynomial function of variable $s_{i}$, and captures the possibility of variable returns to scale for each industry $j$. Taking the logarithm, Equation 1 becomes

$$
\begin{equation*}
y_{i}=a_{j}+\lambda_{j}\left(E T C_{i}\right)+g_{j}\left(s_{i}\right) \quad \text { with } g_{j}\left(s_{i}\right)=s_{i} \cdot f_{j}\left(s_{i}\right) \tag{2}
\end{equation*}
$$

${ }^{1}$ Hereafter lower case letters denote the logarithm form of the capital letters' variables.

Notably, if $f_{j}\left(s_{i}\right)$ is a polynomial of order $n$ then Equation 2 can be further simplified to

$$
\begin{equation*}
y_{i}=a_{j}+\lambda_{j}\left(E T C_{i}\right)+\sum_{\rho=1}^{n+1} \tau_{\rho i} S_{i}^{\rho} \tag{3}
\end{equation*}
$$

If $\tau_{\rho i} \neq 0$ for all $\rho>2$, then variable returns to scale cannot be rejected. However, if $\tau_{1 i} \neq 0$ but $\tau_{\rho i}=0$ for all $\rho>2$, then the production function has the fixed returns' property and, in fact, the constant returns to scale provided that $\tau_{1 i}=1$. We define returns to scale as the elasticity of output with respect to firm size, i.e.,

$$
\begin{equation*}
R_{i}(s) \equiv \frac{\partial y_{i}}{\partial s_{i}}=\sum_{\rho=1}^{n+1} \rho \cdot \tau_{\rho i} s_{i}^{\rho^{-1}} \tag{4}
\end{equation*}
$$

our measure of variable returns for each industry is, $R_{i}(s)$, thus only constrained to be some polynomial of order $n$.

Using the concept of total factor productivity and eliminating the effect of the embodied technical change, we examine size-efficiency relations by constructing an efficiency index defined as

$$
\begin{equation*}
E F F_{i} \equiv y_{i}-\lambda_{j}\left(E T C_{i}\right)-s_{i} \tag{5}
\end{equation*}
$$

Each sector's optimal firm size can thus be determined by comparing the EFF indices between different size classes of firms. Thus, in this paper the optimal firm size is defined as the one with the highest EFF index. Equations 3, 4 and 5 are the basic equations used for our empirical estimations in Section V.

## IV. DATA AND THE ESTIMATION METHOD

## Data

The data used herein originated from The Report on 1991 Industrial and Commercial Census for Taiwan-Fukien Area published by Directorate-General of Budget, Accounting and Statistics, Executive Yuan, The Republic of China. The definitions of variables are found in the Appendix. The census has been conducted every five years since 1954, the most recent issue available covering 1991. However, due to data limitations for the measure of embodied technology change, we look only at data for manufacturing establishments in 1991. For that year, the census documents 146086 manufacturing establishments, comparing 2622934 employees and a total output value of NT\$1610 (US\$62) billion. Measuring by establishment unit, the mean value of total output is NT\$5 155000 , while the average size is 18 employees. Gross value added per person is NT\$287000, and the net value of assets in operation per person is

NT\$1 390000 with an average rate of automation at $38 \%$. Value added per dollar sale is 0.15 , and the average share of exports in firm's total sales is $28 \%$. In general, the size of Taiwan's manufacturing firms (in conventional terms of the number of employees) is rather small. Approximately $90 \%$ of establishments employ fewer than 30 persons, and $97.88 \%$ have less than 100 employees.

As for two-digit industries, 22 classifications are in the report. For our purposes herein we omit tobacco manufacturing and petroleum and coal products industries from our sample since those industries are public-owned enterprises and enjoy a monopolistic position. ${ }^{2}$ Table 1 lists the sample mean values by establishments for the two-digit industries. For these two-digit industries, electrical and electronic machinery, leather and fur products, and transport equipment have the largest share in gross value added. Chemicals, electrical and electronic machinery, and leather and fur products have the largest scale in terms of employed workers. Basic metals, machinery and equipment, fabricated metal products, and printing processing have the highest labour productivity. Chemical, basic metals, and food industry have the greatest capital labour ratio. Printing processing, fabricated metal products, and furniture and fixtures have the highest value added per dollar of sale. Precision instruments, furniture and fixtures, leather and fur products, wearing apparel, and electrical and electronic products have export shares exceeding $50 \%$ of total production. Finally, textile mill products, basic metals, pulp and paper products, and chemicals show the greatest degree of automation.

## Estimation method

For estimation purpose, the embodied technical change described in Equation 1 is further decomposed into two components: the effects of vintage capital and accumulated learning by doing. The vintage capital effect is captured by using dummy variable of automation ( $A U T O=1$ if automation machinery is used or $A U T O=0$ otherwise). The effect of accumulated learning by doing from operating machinery is captured by the ratio of accumulative depreciation to total value of the machinery $(A C C U)$. The larger the value implies the longer the machine is used and, hence, the greater effect on learning by doing is expected to obtain. Both variables are expected to have a positive sign.

In this paper the firm size is defined as a weighted combination of labour and capital. In estimating Equation 3, the weight parameter $\alpha_{j}$, a value between zero and one, is estimated by a nonlinear least squares method using the Marquardt iterative method. ${ }^{3}$ The order of polynomial of

[^0]Table 1. Mean values of statistics
variable returns $(n)$ is determined by finding the order form specification that has the minimum residual sum of squares or the contribution of reducing sum of square is less than $10^{-8}$ by adding one higher order (the initial value for $n$ is zero). For those variable returns' cases, an order of three or below can generally be found. Hence, the returns to scale measure $R(s)$ are generally a polynomial of order two of the firm size, that is, it is either a concave or a convex curve.

## V. ESTIMATION RESULTS

## Aggregate manufacturing level

As expected, Table 2 reveals that the coefficients of both variables of embodied technical change show positive signs and statistically significant $(A U T O=0.1273, \mathrm{SE}=0.0047$; $A C C U=0.2918, \mathrm{SE}=0.0065)$. This finding implies that significant embodied technological change has occurred in Taiwan's manufacturing industry. Tests of null hypothesis of constant returns by using Cobb-Douglas production function or variable return's formulation are all rejected whether or not we consider embodied technical change (Regressions 1 and 2). Nonlinear estimates of variable returns indicate that the returns to scale are a polynomial function of firm size with an order of three (Regression 3).

If we further run regressions for nonexporting and exporting firms separately (Regressions 4 and 5), we find that value of $\alpha$ for exporting firms is nearly twice than that for nonexporting firms. However, the effect of embodied technical change (measured by $A U T O$ and $A C C U$ ) is lower for exporting firms than for nonexporting firms, and the effect of accumulated learning for nonexporting firms is around three times that of exporting firms. Those results imply that production technology is quite different between exporting and nonexporting firms.

Tests of constant returns to scale for the two types of firm are still rejected. Variable returns with order three in firm size are also found for the two types of firm. Figure 1 depicts the measure of variable returns to scale, $R(s)$, as defined in Equation 4. A U-shaped curve of $R(s)$ is found in which exporting firms have a higher magnitude than nonexporting firms everywhere except in the middle range of firm size where constant returns are prevailed. We further confined our sample to exporting firms only. By adding variable of export share to total output ( $E X$ ) (Regression 6) we find a negative and significant effect for the export share variable $(-0.0354, \mathrm{SE}=0.0175)$. This is certainly puzzling, given the conventional wisdom that exporting goods abroad should have a positive effect on productivity. Nevertheless, if we add an interaction term between export share and our index of firm size (denoted by $s$ ), a weighted combination of labour and capital, for the interaction term, then the coefficient of export share is positive $(0.1836, \mathrm{SE}=0.0779)$ and that of the interaction term is negative $(-0.0428$,

Notes: Numbers in the parentheses are standard deviation.
For $L N S$ variable, the null hypothesis is that the estimated parameter equals to one.
*, \# , and ${ }^{+}$indicate statistical significance at $1 \%, 5 \%$, and $10 \%$ levels, respectively.

Fig. 1. Variable returns to scale
$\mathrm{SE}=0.0148)($ Regression 7). Therefore, the firm size cannot be too large to guarantee a positive effect from exporting. The estimated ceiling for the firm size is $\operatorname{Ln} S=4.3$, smaller than the median value of firm size for the sample of 4.6.

This result suggests that in order for trade to have a positive effect on firm's production, the firm should be small in terms of our weighted Cobb-Douglas measure. Most importantly, this measure also allows different combinations of capital and labour that satisfy the required standard for positive trade effect. For instance, for a firm with a median value of capital, the minimum required number of worker falls to less than ten employees. Meanwhile, for a firm with median value of labour the required value for capital is less that NT\$1 164000.

## $T$ wo-digit industry

Our study includes 20 industries in the two-digit industrial classification. Table 3 summarizes the estimation results at this level. Tests of constant returns are not rejected for most two-digit industries, the exceptions being food, textiles, chemicals, plastic products, and basic metals industries. Estimates based upon the variable returns specification also confirm this finding. Among the six increasing returns industries, a polynomial of order three in firm size is found for food textiles, chemicals, and basic metals industries and an order of four is found for chemical products and plastic products industries.

Firms found to be subject to increasing returns are generally noted to have higher $\alpha$ values (i.e., are more capital intensive than firms subject to constant returns). The only exceptional case of the constant returns' industries is the electrical and electronic machinery which has a $\alpha$ value of 0.2247 comparable to that of the increasing returns industries. As for embodied technical change measured by $A U T O$ and $A C C U$, the vintage capital effect is highest for chemicals, food, nonmetallic minerals, leather, machinery, and electrical and electronic machinery industries; in turn the effect of embodied learning by doing is highest for printing processing, paper and paper products, leather, fabricated metal products, plastic products, rubber products, textiles, and chemicals industries.

According to previous estimates obtained for aggregate manufacturing, production technologies may be different for exporting and nonexporting firms. If we distinguish between exporting and nonexporting firms and run regressions for each type of firm, as in the aggregate level from Tables 4 and 5, nonexporting firms are generally found to have greater embodied technical change, except for chemicals and chemical products industries where the effect of accumulated learning by doing for exporting firms is four times that for nonexporting firms. However, $\alpha$ values are higher for exporting firms in all industries, i.e., for the same firm size exporting firms tend to be relatively more capital intensive. For exporting firms in all except for the food

Notes: See notes in Tables 2 and 3.
industry, constant returns to scale cannot be rejected, while for nonexporting firms food, chemical, and plastic products industries are still found to exhibit increasing returns. These findings in two-digit industry level in contrast to what we have found in aggregate manufacturing level in the previous section where the magnitude of returns to scale measure is higher for exporting firms as shown in Fig. 1.

## Existence of industry-wide technology spillovers

In light of this clear contrast, we briefly return to aggregate analysis. These results apparently suggest that a certain form of technology spillover effects may exist among exporting firms in the same industry. Chuang (1996) estimated that approximately $40 \%$ of output growth of Taiwan's manufacturing during 1975-90 has due to trade-induced learning by doing. By using the volume of exports $(L N E)$ and total volume of other firms' exports of the industry (SPOR) as an additional variable capturing spillover effects across exporting firms within the same industry, for the entire manufacturing industry, we find that

$$
L N Y=3.2512+0.1135 A U T O+0.0972 A C C U
$$

$$
\begin{aligned}
& \text { (0.0935) }(0.0128) \\
& +0.9073 L N S+0.0990 L N E+0.0160 S P O R \\
& \quad(0.0109)
\end{aligned}
$$

$$
\alpha=0.2843, N=8593, R^{2}=0.9970
$$

Both firm-specific learning and industry-wide spillover effects are positive and significant. Moreover, industry-wide spillover effect across firms within the same industry is approximately one-sixth of the firm-specific export-induced learning effect. Notably, by including the effect of exportinduced learning, increasing returns disappears in aggregate manufacturing data as well.

## Productive efficiency and optimal firm size

This subsection further examines the relations between productive efficiency and optimal firm size for each twodigit industry. Firms are first divided and ranked from one to ten according to firm size, $s .^{4}$ An index of productive efficiency is calculated according to Equation 5 for each firm and the mean values of the productive efficiency of each class are presented in Table 6. In particular, optimal firm size appears large for food, textile products, furniture and fixtures, printing processing, chemicals, nonmetallic mineral products, and transport equipment, while small optimal size is found only in the wearing apparel industry.

Earlier results from Tables 4 and 5 reveal that the effects of embodied technical change and returns to scale are quite different for exporting and nonexporting firms. If we further decompose the two-digit industry classification (as before at the aggregate level) sample into exporting firms and nonexporting firms, optimal firm sizes are rather different for the two types of firm (see Tables 7 and 8). Although the mean value of firm size is relatively larger for exporting firms than for nonexporting firms, interesting comparisons arise between the two groups. For food, textiles, chemicals, and chemical products industries, optimal firm size is small for exporting firms but is large for nonexporting firms. For machinery, electrical and electronic machinery, transport equipment, and precision instrument industries, optimal firm size is found to be small for both types of firm. As a whole, our estimations clearly indicate that for exporting firms, small firm size has an efficiency advantage over a large one. This may account for why small- and mediumsize enterprises take a majority share in Taiwan's total exports and they are the major contributions to Taiwan's economic growth. Our findings also suggest that a large technology spillover effect among firms and across industries is the most likely reason for efficiency in small-scale production.

## VI. CONCLUDING REMARKS

Taiwan's firm data reveal that weak increasing returns exist for aggregate manufacturing industry. Returns to scale are a U-shaped curve with respect to firm size, and their magnitude is higher for exporting firms than for nonexporting ones. Moreover, export is beneficial only if the firm remains small. In contrast, for the two-digit industry constant returns to scale prevail for most of the industries particularly for the case of exporting firms. This evidence, as the finding from time series data (see, for example, Chuang, 1996), suggests that certain form of technology spillovers exists among firms and across industries. We find that industrywide spillover effect across firms is approximately one-sixth of the firm-specific export-induced learning effect. These findings correspond to the hypothesis of endogenous growth models posting 'constant returns learning spillover technology' (see, for example, Stokey, 1988; Young, 1991; and Lucas, 1993).

As for size-efficiency relations, evidence clearly indicates that optimal firm size for exporting firms is small in most industries, particularly the highly export-oriented ones. Electrical and electronic machinery, precision instruments, machinery and equipment, rubber products, food, leather and fur products, and textiles industries are prime examples. This finding helps account for why small- and medium-sized

Notes: See notes in Table 6.
enterprises comprise over $90 \%$ in Taiwan's manufacturing industry.

In sum, the findings in this study provide valuable insight into Taiwan's economic development which is remarkable but not unique. The estimated $U$-shaped curve of returns to scale suggested that another development path may exist wherein optimal firm size is larger, and in which trade may or may not be good for economic development. However, evidence from Taiwan's development experience provides
a good example for developing countries: initial conditions such as small firm size and production of labour intensive goods need not be anti-thetical to growth; by contrast they, along with policies to open trade to international markets, may serve as keystones in development strategies leading to a successful process of industrialization and sustainable economic growth. As our measure of firm size allows different combinations of capital and labour that satisfy the required standard for positive trade effect, there may exist
significant variations for the values of required capital and labour. Therefore, a close investigation of these values and the regimes in which most Taiwanese firms appear to have operated, are surely areas for future study.

## ACKNOWLEDGEMENTS

I am grateful to an anonymous referee for very helpful comments and to the National Science Council of Taiwan for Financial support (NCS85-2415-H-004-002).

## APPENDIX: DEFINITIONS OF VARIABLES

| $A C C U$ | Accumulated depreciation as the share of machinery. |
| :---: | :---: |
| AUTO | 1 for using automation machinery, 0 for not using automation machinery. |
| DUMEX | 1 for exporting firms, 0 for nonexporting firms. |
| EX | Share of exports to total production. |
| EXLNS | Product of EX and LNS. |
| EFEF | An index of productive efficiency. |
| LNY | Logarithm form of value-added. |
| LNK | Logarithm form of net asset. |
| LNL | Logarithm form of workers employed. |
| LNS | Logarithm form of firm size, where $L N S=\alpha L N K+(1-\alpha) L N L .$ |
| LNE | Logarithm form of value of exports. |
| SPOR | Logarithm form of total value of other firm's exports within the same industry. |

Source: The Report on 1991 Industrial and Commercial Census for Taiwan-Fukien Area, Directorate-General of Budget, Accounting and Statistics, Executive Yuan, The Republic of China.

[^0]:    ${ }^{2}$ The twenty two-digit industries are food, textile mill products, wearing apparel and accessories, leather and fur products, wood and bamboo products, furniture and fixtures, pulp, paper and paper products, printing processing, chemicals, chemical products, rubber products, plastic products, non-metallic mineral products, basic metals, fabricated metal products, machinery and equipment, electric and electronic machinery, transport equipment, precision instruments, and miscellaneous manufactured products industries.
    ${ }^{3}$ The convergence criterion is set that the changes in loss function satisfied (LOSS ${ }^{i-1}-$ LOSS $\left.^{i}\right)\left(\right.$ LOSS $\left.^{i}+10^{-6}\right)<10^{-8}$.

[^1]:    ${ }^{4}$ In the sample, our measure of firm size $(s)$ has a correlation coefficient of 0.9714 with the conventional proxy of the number of employees. There are eleven instead of ten classes for exporting firms.

[^2]:    Notes: Ten class sizes have been defined from 1 to 10 by breaking down the logarithms of size $(S)$. Numbers in the parentheses are numbers of establishment.

[^3]:    Notes: See notes in Table 6.
